DOCUMENT-IDENTIFIER: US 5231019 A

TITLE: Transformation of hereditary material of plants

Detailed Description Text (107):

Protoplasts of *Lolium multiflorum* (Italian ryegrass) are taken up at a concentration of 2.10×10^6 per ml in 1 ml of 0.4 molar mannitol at pH 5.8. To this suspension are added, in succession, 0.5 ml of 40% polyethylene glycol (PEG) with a molecular weight of 6000 in modified (pH 5.8) F medium [Nature 296, 72-74 (1982)], and 65 μ l of an aqueous solution containing 15 μ g of the plasmid pABDI and 50 μ g of calf thymus DNA. This mixture is incubated for 30 minutes at 26 degree C. with occasional agitation and subsequently diluted with F medium, as described in Nature 296 (1982), 72-74. The protoplasts are isolated by centrifugation (5 minutes at 100 g) and taken up in 4 ml of CC culture medium [Potrykus, Harms, Lorz, Callus formation from cell culture protoplasts of corn (*Zea Mays* L.), Theor. Appl. Genet. 54, 209-214 (1979)] and incubated in the dark at 24 degree C. After 14 days the developing cell cultures are transferred to the same culture medium, but with the the antibiotic G-418 (commercially available; GIBCO EUROPE Product Catalogue, Catalogue No. 0661811). G-418 is toxic to *Lolium* cells at a concentration of 25 mg/l and permits solely the further development of cells which have taken up the bacterial gene for kanamycin resistance. G-418 is a kanamycin analog with substantially better activity in graminaceous cells than kanamycin itself. Resistant cell colonies are transferred to agar medium (the same medium as above, 25 ml/l G-418, without osmoticum) and, after reaching a size of several grams fresh weight per cell colony, analysed for the presence of the bacterial gene and for the biological activity of the gene. The former analysis is made by hybridisation of a radioactively labelled DNA sample of the gene with DNA which has been isolated from the cell culture; while the latter is made by detecting the enzyme activity by phosphorylation of kanamycin with radioactive ATP. Both molecular analyses yielded unequivocal proof of the genetic transformation of the cell colonies which had been selected on G-418. The assays constitute the first proof of the genetic transformation of protoplasts of graminaceous plants and furthermore prove that, in principle, protoplasts of grasses can be genetically manipulated by the described process. The possibility of genetically manipulating cultivated grasses, for example cereals, is thus also afforded.

TITLE: Ryegrass endophytes.

Detailed Description Text (26):

Ryegrass seeds containing endophyte were surface sterilized by soaking for 20 minutes in 50% sulphuric acid followed by rinsing several times in sterile water, soaking in 10% sodium hypochlorite solution for 20 minutes and rinsing again in sterile water. All surface sterilized tissues were placed on potato dextrose agar containing antibiotics (100 .mu./ml streptomycin+100 .mu.g/ml penicillin) in Petri dishes and incubated at 20.degree. C. for 4-5 weeks. By this time colonies of endophytes had sufficient growth to enable them to be used for inoculating grass seedlings.

L4 ANSWER 1 OF 10 BIOSIS COPYRIGHT 2003 BIOLOGICAL ABSTRACTS INC.

AB A multiple-antibiotic resistant *E. coli* was applied to rye-grass covered field mini-plots to simulate point-source contamination. Using three mini-plots for testing and a fourth as a control, the ability of the tracer bacterium to survive under field conditions was studied. Three test plots each received separately 10⁷, 10⁸, or 10¹⁰ cfu mL⁻¹ *E. coli* grown for 24 h in 5 L one-third strength Tryptic soy broth. In Phase I of the study, it was determined that the tracer disappeared from leaf surfaces of rye-grass covering the plots after 41 days. In Phase II, determination of the presence of the tracer in the top 2" (5 cm) of soil after two months elapsed time indicated that tracer cfu/g dry wt. of soil had declined five, three, and three-logs for test plots 1, 2, and 3. In Phase III, subsurface soil sampling using a soil auger on the three test mini-plots indicated the tracer had penetrated through the top-soil and into the underlying B horizon (20 to 50 cm down). In Phase IV, detailed sampling by excavation of the subsurface soil Horizons of the third test mini-plot showed that the tracer had also penetrated through the hardpan (C Horizon) located 0.6 m below the surface to enter the groundwater (1.06 m deep) (Phase V). *E. coli* counts fell precipitously to 10⁻³ cfu g⁻¹ in soil and then, in the groundwater at the groundwater-soil interface, persisted at a concentration of 10⁻³ cfu 100 mL⁻¹ for 2 yr. As time past, tracer counts fell to 145 cfu/100 mL in 6 yr rose to 820 cfu 100 mL⁻¹ in 1986 (8 yr elapsed time), and then fell to 25 cfu 100 mL⁻¹ in 1991 after 13 yr. Serotyping of 1986 *E. coli* isolates indicated that 62% were of the original tracer serotype (0.128:B12) while only 43% of the 1991 isolates were of the same serotype. The penetration rate of the tracer down through the mini-plot soil into the groundwater was 0.02 m day⁻¹ while downslope dispersion occurred at an estimated rate of 1.0 m day⁻¹. The implications of the above findings are discussed.

L4 ANSWER 3 OF 10 BIOSIS COPYRIGHT 2003 BIOLOGICAL ABSTRACTS INC.

AB The corynetoxins, toxic metabolites of *C. rathayi* formed in galled seed-heads of infected annual ryegrass, *L. rigidum*, are new members of the tunicamycin group of **antibiotics**. They consist of N-acetylglucosaminyl-tunicaminy-uracil in amide linkage with fatty acids which differ in certain respects from those present in the tunicamycins. The corynetoxin acids are of slightly longer chain length, C15-C19, occur in a .beta.-hydroxy as well as saturated and .alpha., .beta.-unsaturated series, and have anteiso, iso and normal chain terminations. .beta.-Hydroxy acids have not been observed previously in the tunicamycin group and anteiso chains were reported only recently in the streptovirudin subgroup. Stereochemical identity of the C11-amino sugar in the corynetoxins with the tunicamine part of the tunicamycins is demonstrated by formation of a common hydrolysis product, di(N-trifluoroacetyl)glucosaminyl-tunicaminy-uracil. Analysis of the ¹³C and proton NMR spectra of the main components, corynetoxins H17a and U17a, confirms the stereochemistry proposed for tunicamine, except that the glycosidic linkages are changed to .alpha.-galactosamine, .beta.-glucosamine.

L4 ANSWER 4 OF 10 BIOSIS COPYRIGHT 2003 BIOLOGICAL ABSTRACTS INC.

AB The biological activities of corynetoxins, the causative agents of annual ryegrass toxicity [a disease of grazing livestock], were compared with those of the closely related tunicamycins and found to be essentially identical. They showed similar **antibiotic** activity against Newcastle disease virus and a range of gram-positive bacteria. In preparations of rat liver rough microsomes they strongly inhibited the uridine diphospho-N-acetylglucosamine:dolichol-P N-acetylglucosamine-1-phosphate transferase, an enzyme essential for N-glycosylation of glycoproteins. Pretreatment of rats with corynetoxins resulted in dose- and time-related reduction in the level of activity of this transferase in liver microsomal preparations. The implications of this reduction are discussed with reference to annual ryegrass toxicity, the only field disease known to be caused by tunicamycin-related compounds. Corynetoxin and tunicamycin produced similar neurological effects and increased vascular permeability in nursing rats; they showed similar LD50 of 137 and 132 .mu.g/kg, respectively, in the nursing rats.

AB Thirty-six newborn Guernsey and Jersey calves were allotted to 6 groups which were identical as to sex and breed and similar in wt. and height at withers. The system included confinement in individual pens and feeding of pure colostrum through 4 days of age, one-half colostrum and one-half skim milk through 21 days, and skim milk until calves were 60 days old. All milks were fed at the rate of 9% of body wt., 2 equal portions daily. Chopped alyce clover hay and mixed concentrates were offered, free choice. Methionine and K orotate, each 220 mg./100 lb. body wt., were fed to all subjects other than the controls. Chlortetracycline, 45 or 90 mg./100 lb. live wt., or 1 of the other antibacterial agents was dispersed in the milk fed to calves, as follows: group 3, chlortetracycline; group 4, p-aminosalicylic acid (PAS); group 5, isoniazid, and group 6, erythromycin. Daily records included observations on general health and consumption of feed. Body wts. and heights at withers were recorded on the 4th-day postpartum and at weekly intervals thereafter. All calves were sleek and alert, and no differences in appearance between groups were discernible. Av. gains in body wt. were higher in all treated calves than in the controls. However, these differences were not statistically significant. Changes in height at withers and efficiency of feed utilization appeared to be unaffected by any of the supplements.

AB Two UK grassland soils, one from Rothamsted (24% clay) and the other from Woburn (8% clay) were incubated at 25degreeC, unamended or amended with **ryegrass** followed by fumigation 20 d later followed by a further 20 d incubation. Other portions of the Rothamsted grassland soil were treated separately with a fungicide (Captan), a bacteriocide (Bronopol), or a herbicide (Dinoseb). The substrate-induced respiration (SIR) method coupled with use of **antibiotics** (selective inhibition) and biovolume measurements by direct microscopy were used to comparatively measure total microbial biomass and the proportions of fungal and bacterial biomass in these two treated soils. Both methods gave similar estimates of total microbial biomass and the proportions of bacteria and fungi in the two soils. The different treatments did not significantly change the proportions of bacteria and fungi in the soil microbial biomass. It was concluded that both SIR and biovolume measurements are equally valid in measuring total biomass as are selective inhibition and biovolume measurements in measuring the proportions of fungi and bacteria in soils which are either unamended or undergoing rapid changes in metabolism due to substrate amendment, fumigation or biocidal treatments.

L8 ANSWER 2 OF 34 CA COPYRIGHT 2003 ACS

AB Under field conditions annual **ryegrass** toxicity in sheep is seen principally as an acute neurol. disturbance with high morbidity and mortality rates. It is caused by the ingestion of corynetoxins produced by the bacterium, *Clavibacter toxicus*, which infects seed heads of annual **ryegrass**, *Lolium rigidum*. These toxins are closely the tunicamycin group of **antibiotics** both structurally and in biol. activity. The possibility of an assocn. between annual **ryegrass** toxicity and infertility in sheep arose several years ago from anecdotal reports by farmers in South and Western Australia of lambing rates being severely depressed in the breeding season following an outbreak of the disease. To investigate this, an initial series of expts. were carried out in rats, using tunicamycin because of its com. availability. It was shown that large doses of tunicamycin did not affect the reproductive performance of females, but in males doses insufficient to produce significant clin. signs induced destruction of seminiferous tubule epithelium and led to permanent testicular atrophy. Here we report the extension of this investigation to the effect of tunicamycin on the semen and reproductive tract of rams.

AB Corynetoxins, the causative agents of annual **ryegrass** toxicity, and tunicamycins are members of the tunicaminy-uracil **antibiotic** group and are specific inhibitors of the enzyme, uridine diphospho N-acetylglucosamine:dolichyl phosphate (N-acetylglucosamine-1-phosphate) transferase. It has been shown that in sheep treated parenterally with a single dose of tunicamycin, there is a time- and dose-dependent decrease in liver microsomal GlcNAc-1-P transferase activity. This study was undertaken to measure the time taken for GlcNAc-1-P transferase activity to return to normal after inhibition by a single s.c. dose of tunicamycin. The study was done in two species: sheep, which are sensitive to the toxins and adult female rats, which are about 15-fold more resistant to lethal tunicamycin poisoning than sheep and about 50% more resistant than male rats.

AB The neurological disease of livestock known as annual **ryegrass** toxicity, caused by ingestion of bacterial toxins called corynetoxins, has been shown to be produced experimentally by injection of tunicamycin, a related **antibiotic**. In this study the effects of tunicamycin inhibition on the activity of the enzyme, N-acetylglucosamine-1-phosphate transferase, in sheep liver rough microsomes were measured in vitro and in vivo. Enzyme activity was dependent on Triton X-100 and exogenous dolichyl phosphate for maximal activity, although there was measurable activity in their absence. The transferase enzyme was very sensitive to in vitro (inhibition can be detected below 10 ng ml⁻¹). In vivo, sheep treated parenterally with a single dose of tunicamycin showed a time and dose-dependent decrease in enzyme activity, which was almost completely inhibited for up to 14 days after a sublethal dose of toxin. In addition, the yield of rough microsomes was lower from toxin-treated sheep than from control animals.

AB A set of 25 different media, selected for their ability to support the growth of a large number of bacteria, yielded between four to seven times more morphologically distinct bacteria from **ryegrass** and alfalfa roots and soil samples when used for plate counting than a single medium. The 25 media in the selection included some of the commonly used media supplemented with **antibiotics** or toxicants and media containing only a single nutrient. Media used singly included King's B, Luria-Bertani, Nutrient Agar, Tryptic Soy Agar, and Cold-extracted Soil Extract Agar. Based on the results of this study we recommend the use of a set of different media, as opposed to one or two media, in order to increase the efficiency of plate counting method for estimating bacterial diversity.

L8 ANSWER 6 OF 34 MEDLINE DUPLICATE 3
AB Tunicamycin belongs to a group of **antibiotics** which can cause severe and often fatal neurological malfunction in animals, commonly known as "annual **ryegrass** toxicity." At the cellular level, tunicamycin is a potent glycosylation inhibitor which is often used to elucidate the importance of glycosylation in protein functions. Earlier reports suggested that tunicamycin was able to interfere with the binding of nerve growth factor to its receptors. In this report, we showed that tunicamycin was able to kill sympathetic neurons in cultures. The mechanism of cell death was observed to be similar to that of "programmed cell death" in sympathetic neurons induced by nerve growth factor deprivation. Such tunicamycin-induced cell death could be prevented by the protein synthesis inhibitor cycloheximide, which was known to prevent the programmed cell death in sympathetic neurons. These results demonstrated that, in addition to the proven CNS neurotoxicity in animals, tunicamycin causes programmed cell death in peripheral (sympathetic) neurons.

L8 ANSWER 7 OF 34 MEDLINE DUPLICATE 4
AB Plant toxins are the chemical defenses of plants against herbivory. Grasses have relatively few intrinsic toxins, relying more on growth habit to survive defoliation and endophytic fungal toxins as chemical defenses. Forage grasses that contain intrinsic toxins include *Phalaris* spp. (tryptamine and carboline alkaloids), sorghums (cyanogenic glycosides), and tropical grasses containing oxalates and saponins. Toxic effects of these grasses include neurological damage (*Phalaris* staggers), hypoxia (sudangrass), saponin-induced photosensitization (*Brachiaria* and *Panicum* spp.), and bone demineralization (oxalate-containing grasses). Endophytic toxins in grasses include ergot alkaloids in tall fescue and tremorgens (e.g., lolitrem B) in perennial **ryegrass**. Lolitrems cause neurological effects, producing the **ryegrass** staggers syndrome. Annual **ryegrass** toxicosis is caused by corynetoxins, which are chemically similar to tunicamycin **antibiotics**. Corynetoxins are produced by *Clavibacter* bacteria that parasitize a nematode, *Anguina agrostis*, that may infect annual **ryegrass**. Corynetoxins inhibit glycoprotein synthesis, causing defective formation of various blood components of the reticulo-endothelial system. Another mycotoxin in **ryegrass** is sporidesmin, which causes liver damage and secondary photosensitization (facial eczema). *Fusarium* toxins such as zearalenone and trichothecenes also occur in forage grasses. Kikuyugrass poisoning results in severe damage to the ruminal epithelium and omasal mucosa, and neurological signs. The causative agent, which may be associated with army worm predation of the grass, has not been identified. The properties and significance of these toxins are reviewed.

AB A multiple-antibiotic resistant *E. coli* was applied to **rye-grass** covered field mini-plots to simulate point-source contamination. Using three mini-plots for testing and a fourth as a control, the ability of the tracer bacterium to survive under field conditions was studied. Three test plots each received separately 10⁷, 10⁸, or 10¹⁰ cfu mL⁻¹ *E. coli* grown for 24 h in 5 L one-third strength Tryptic soy broth. In Phase I of the study, it was determined that the tracer disappeared from leaf surfaces of **rye-grass** covering the plots after 41 days. In Phase II, determination of the presence of the tracer in the top 2" (5 cm) of soil after two months elapsed time indicated that tracer cfu/g dry wt. of soil had declined five, three, and three-logs for test plots 1, 2, and 3. In Phase

III, subsurface soil sampling using a soil auger on the three test minei-plots indicated the tracer had penetrated through the top-soil and into the underlying B horizon (20 to 50 cm down). In Phase IV, detailed sampling by excavation of the subsurface soil Horizons of the third test mini-plot showed that the tracer had also penetrated through the hardpan (C Horizon) located 0.6 m below the surface to enter the groundwater (1.06 m deep) (Phase V). E. coli counts fell precipitously to 10-3 cfu g-1 in soil and then, in the groundwater at the groundwater-soil interface, persisted at a concentration of 10-3 cfu 100 mL-1 for 2 yr. As time past, tracer counts fell to 145 cfu/100 mL in 6 yr rose to 820 cfu 100 mL-1 in 1986 (8 yr elapsed time), and then fell to 25 cfu 100 mL-1 in 1991 after 13 yr. Serotyping of 1986 E. coli isolates indicated that 62% were of the original tracer serotype (0.128:B12) while only 43% of the 1991 isolates were of the same serotype. The penetration rate of the tracer down through the mini-plot soil into the groundwater was 0.02 m day-1 while downslope dispersion occurred at an estimated rate of 1.0 m day-1. The implications of the above findings are discussed.

 AB Agrobacterium radiobacter K84 is an effective, commercially applied, biological control agent for the plant disease crown gall, yet little is known about the survival and dissemination of K84. To trace K84 in the environment, spontaneous antibiotic-resistant mutants were used. Growth rates and phenotypes of streptomycin- or rifampin-resistant K84 were similar to those of the parental K84, except the rifampin-resistant mutant produced less agrocin 84 as determined by bioassay. K84 and a strain of Agrobacterium tumefaciens established populations averaging 10(5) CFU/g in the rhizosphere of cherry and persisted on roots for 2 years. K84 established rhizosphere populations between 10(4) and 10(6) CFU/g on cherry, ryegrass, and 11 other herbaceous plants. Populations of K84 declined substantially in fallow soil or water over a 16-week period. K84 was detected in the rhizosphere of ryegrass located up to 40 cm from an inoculum source, indicating lateral dissemination of K84 in soil. In gall tissue on cherry, K84 established populations of 10(5) CFU/g, about 10- to 100-fold less than that of the pathogen. These data demonstrate that K84 persists for up to 2 years in a field environment as a rhizosphere inhabitant or in association with crown gall tissue.

AB A *Streptomyces* sp. has been isolated from perennial **ryegrass** seedling tissues from which it emerged in liquid culture after surface sterilization of seed. In submerged fermentation the *Streptomyces* produced 1-N-methylalbonoursin (1), a fluorescent and weakly **antibiotic** metabolite which was identified by ms and X-ray crystallography and further characterized by, uv, 1H-, and 13C-nmr spectroscopy. The biosynthesis of the diketopiperazine skeleton of compound 1 from leucine and phenylalanine was demonstrated. A close affinity of the *Streptomyces* sp. with *Streptomyces albus*, from which this metabolite was first isolated, is implied. The possibility that the *Streptomyces* sp. should be recognized as an endophyte of **ryegrass** is discussed.

 AB Populations of *Thielaviopsis basicola* decreased during the first 2 weeks
 following introduction in soils planted to bean [*Phaseolus vulgaris*
 (host)], rye [*Secale cereale*] (nonhost), and in fallow
 soil, then began to increase in soils planted to beans. The increase in
 numbers was associated with increase in lesions on the surface of bean
 roots. Pathogen populations in soils planted to rye decreased as compared
 to fallow soil. Extracts from soil in which rye had been decomposing for
 30 days or longer inhibited the growth of *T. basicola*. In soil containing
 decomposing rye residues the severity of root rot caused by *T. basicola* was
 reduced in subsequently planted highly susceptible tobacco cv. Coker.
 Indigenous soil bacteria, of which 68% were antagonistic to *T. basicola*,
 increased during decomposition of rye residues. It appears that the
 disease suppressing effects of rye occur during its growth and during its
 decomposition and is associated with microbial antagonisms and
 antibiotic production with rye as substrate.

 AB A pathogenic *Pseudomonas syringae* strain resistant to rifampicin and
 nalidixic acid was sprayed upon and colonized maple twigs and perennial
 ryebrass. The inoculated twigs were sampled at intervals of 2-3 weeks from
 July 1985 to September 1986, and epiphytic populations of the marked
 strain recovered during this time ranged from undetectable to 104
 colony-forming units/g. The results showed that this strain of *P. syringae*
 could overwinter on maple twigs and potentially serve as a source of
 inoculum in the spring. Aerial dispersal was also investigated. The marked
 strain inoculated onto grass growing in pots was detected on medium in
 inverted petri plates, on maple leaves and with an Andersen sampler
 positioned from 12 to 100 cm above the grass. The number of detectable
 cells that dispersed vertically upwards was low even in the presence of
 wind, rain, or irrigation water. The marked strain inoculated onto maple
 branches was isolated from grasses under the inoculated trees, showing
 that *P. syringae* was dispersed downward. Lateral dispersal of the marked
 strain from inoculated to uninoculated trees was not detected. The
 identity of the antibiotic-resistant strain isolated from the trees and
 grasses was confirmed by DNA restriction-fragment profile analysis.

AB Guinea pigs were injected with tunicamycin and the sequential morphological alterations in the brain examined to investigate further the pathogenesis of cerebral lesions in this experimental model of annual ryegrass toxicity, a central nervous system disease of livestock caused by members of the tunicamycin group of antibiotics. Brain damage was most commonly observed in the cerebellum, and the important alterations in the development of degenerative parenchymal lesions appeared to be largely referable to changes in small blood vessels. Endothelial damage, with increased vascular permeability, resulted in capillary obstruction leading to localised ischaemia and hypoxic neuronal damage. There was evidence for several possible mechanisms which may have contributed to vascular occlusion.

AB A unique mixture of toxic tunicaminylluracil antibiotics, closely related to the corynetoxins which cause annual ryegrass toxicity and to the tunicamycins, has been identified in rain-damaged, stored wheat implicated in a fatal intoxication of pigs. The toxins, present at a level of approximately 4.5 mg per kg, were isolated by preparative t.l.c. They displayed specific inhibition of uridine diphospho-N-acetylglucosamine:dolichol-phosphate N-acetylglucosamine-1-phosphate transferase and bacterial inhibition consistent with this type of antibiotic, and produced symptoms in rats identical with those associated with the tunicamycin and corynetoxin complexes. Chemical identification, based on t.l.c., h.p.l.c., co-chromatography with authentic toxins and catalytic hydrogenation, was confirmed by fast atom bombardment mass spectrometry. The origin of these toxins is unknown, but the unique mixture of components detected suggests a previously unreported tunicaminylluracil antibiotic-producing microbial source.

AB Corynetoxin complex is the family of tunicamycin-like **antibiotics** isolated from annual **ryegrass** (*Lolium rigidum*) seedheads infected with a plant pathogenic *Corynebacterium* and identified as the causative toxins for annual **ryegrass** toxicity (ARGT) in Australia. Only trace amounts of corynetoxins have been reported to be produced in vitro. Enhanced in vitro production of corynetoxins by *Corynebacterium* sp. has now been demonstrated. The important conditions required were growth on an agar surface, absence of light, low incubation temperature and strain of the organism. Strains of the *Corynebacterium* sp. grown under conditions not supporting corynetoxin production failed to produce corynetoxins when subsequently grown under more favourable conditions. Even when maintained under the most favourable conditions, toxigenicity of strains declined on repeated subculturing. While levels of toxin typically produced in vitro were only about 5% of those found in infected **ryegrass** seedheads, they were high enough to be a useful source of corynetoxins for experimental purposes.

AB The effect of inoculation of crested wheatgrass (*Agropyron cristatum* L.), perennial **ryegrass** (*Lolium perenne* L.) and white clover (*Trifolium repens* L.) with the soil diazotroph *Bacillus polymyxa* was studied. Plant growth responses to inoculation varied from slightly negative (perennial **ryegrass**) to highly positive (white clover and crested wheatgrass) when root, shoot and plant dry weights were measured. Root-to-shoot ratios were also increased in the latter species. Seedling emergence in crested wheatgrass was shown to be enhanced by inoculation with the bacterium. Possible mechanisms of the growth response include suppression of pathogenic organisms in the rhizosphere by the inoculant strain, root-associated nitrogen fixation, solubilization of phosphorus compounds or the bacterial production of plant growth-promoting substances. Use of sterilized soil in experiments and a lack of **antibiotic** production by the *Bacillus* render the first possibility unlikely. However, in vitro assays showed the bacterium to possess an active nitrogenase, to be capable of solubilizing organic but not inorganic phosphate compounds, and to produce indoleacetic acid, but not detectable amounts of cytokinins or gibberellins. Experimentation with *A. cristatum* suggested solubilization of P may be involved in enhanced seedling emergence, but neither N fixation nor phosphate solubilization were the primary contributing factors to the observed growth response. The data support the contention that production of growth-promoting compounds similar in activity to indoleacetic acid by the bacterium is the likely stimulus for the observed increase in plant productivity.

AB 1. For the germination of *Secale cereale* caryopses the temperature limit between 13 and 26.degree. C was optimal. The temperature maximum of the length of growth of the coleoptiles and primary leaves as well as that of the breach of the primary leaf through the coleoptile lies near 26.degree. C. 2. Between 13 and 26.degree. C the germination is not influenced by chloramphenicol and from 32 to 38.degree. C it is promoted. The length of growth of the coleoptiles and primary leaves is inhibited by chloramphenicol between 13 and 32.degree. C, but promoted near 38.degree. C. The breach of the primary leaf is inhibited by chloramphenicol between 20 and 32.degree. C and activated near 35.degree. C. 3. Light does not influence the germination, but the coleoptiles and primary leaves are shorter and the breach of the primary leaves takes place in an increased measure. The inhibiting effect of chloramphenicol in the light is by far weaker than in the dark. A. Penicillin does not influence the development of *Secale cereale* caryopses. 5. At temperatures from 32 to 38.degree. C the germination is stimulated by 0,1% solution of bromine.

AB Corynetoxins are the causative agents of annual **ryegrass** toxicity and are found in seed-heads infected by *Corynebacterium rathayi*. Corynetoxins are members of a subclass of nucleoside complexes, and are structurally closely related to the tunicamycin group of **antibiotics**. Corynetoxin and tunicamycin consist of uracil, a C1-amino sugar named "tunicamine", N-acetyl-D-glucosamine and a fatty acid. They differ from each other only in the fatty acid moiety. Two corynetoxins and four tunicamycins, as well as ten analogs, have been synthesized.

AB The effect of gut microflora on the nutritional value of **ryegrass** (*Lolium perenne* L.)-white clover (*Trifolium repens* L.) leaf protein conc. (LPC) was studied. The effects of giving a diet contg. LPC as the main protein source to chickens was compared to the effects of giving a diet contg. heat-treated soybean meal (SBM). Supplementation of the LPC diet with an **antibiotic** (Neomix) improved growth and increased the mean amino acid digestibility by .apprx.70%. Chickens given the diet contg. LPC tended to have a higher level of C19 cyclopropane fatty acid in

the excreta than chickens given the SBM diet. This indicated that consumption of the LPC diet influenced the nature and/or activity of the gut microflora, and that gut microflora influenced the nutritional value of LPC.

AB Definitive evidence is presented for the 1st time for stable gene transfer to cultured cells in a plant of the family Gramineae, *Lolium multiflorum* (Italian **ryegrass**), using DNA transformation of protoplasts from a non-morphogenic cell culture. A construction consisting of expression signals from gene VI of Cauliflower Mosaic virus joined to the aminoglycoside (neomycin) phosphotransferase gene (APH(3')II) from transposon Tn5 conferred resistance to the **antibiotic** G-418 to cell colonies arising from transformed protoplasts. By demonstrating a tight correlation between the resistant phenotype, the physical presence of the foreign gene and the presence of the active gene product we have shown that these colonies are true transformants and that a gene which is expressed well in dicotyledenous plants is also expressed in cells of graminaceous monocots.

AB The corynetoxins, toxic metabolites of *C. rathayi* formed in galled seed-heads of infected annual **ryegrass**, *L. rigidum*, are new members of the tunicamycin group of **antibiotics**. They consist of N-acetylglucosaminyl-tunicaminy-uracil in amide linkage with fatty acids which differ in certain respects from those present in the tunicamycins. The corynetoxin acids are of slightly longer chain length, C15-C19, occur in a .beta.-hydroxy as well as saturated and .alpha.,.beta.-unsaturated series, and have anteiso, iso and normal chain terminations. .beta.-Hydroxy acids have not been observed previously in the tunicamycin group and anteiso chains were reported only recently in the streptovirudin subgroup. Stereochemical identity of the C11-amino sugar in the corynetoxins with the tunicamine part of the tunicamycins is demonstrated by formation of a common hydrolysis product, di(N-trifluoroacetyl)glucosaminyl-tunicaminy-uracil. Analysis of the 13C and proton NMR spectra of the main components, corynetoxins H17a and U17a, confirms the stereochemistry proposed for tunicamine, except that the glycosidic linkages are changed to .alpha.-galactosamine, .beta.-glucosamine.

AB The biological activities of corynetoxins, the causative agents of annual **ryegrass** toxicity, were compared with those of the closely related tunicamycins and found to be essentially identical. Both showed similar **antibiotic** activity against Newcastle disease virus and a range of gram-positive bacteria. In preparations of rat liver rough microsomes they also strongly inhibited the uridine diphospho-N-acetylglucosamine (UDP-GlcNAc):dolichol-P N-acetylglucosamine-1-phosphate (GlcNAc-1-P) transferase, an enzyme essential for N-glycosylation of glycoproteins. Pretreatment of rats with corynetoxins resulted in dose- and time-related reduction in the level of activity of this transferase in liver microsomal preparations. The implications of this reduction are discussed with reference to annual **ryegrass** toxicity, the only field disease known to be caused by tunicamycin-related compounds. Both corynetoxin and tunicamycin produced similar neurological effects and increased vascular permeability in nursing rats and they showed similar LD50-values of 137 and 132 micrograms/kg, respectively, in the nursing rats.

 AB IAA promotes the growth of apical coleoptile segments of *Triticum vulgare*
 'Arthur', *Hordeum vulgare* 'Bonneville 70', *Avena sativa* 'Garry', *Zea mays*
 '#13', and *Secale cereale* 'Balboa'. Red light enhances
 the growth of wheat apical segments but has no significant effect on the
 increase in length of barley, corn, oat and rye segments. Concentrations
 of puromycin dihydrochloride, actinomycin D and streptomycin sulfate which
 allow growth comparable to that in distilled water, markedly inhibit
 stimulation of segment elongation due to either optimal IAA or red light
 (660 nm). Optimal GA and sucrose slightly stimulate apical segment growth.
 There appears to be no interaction of sucrose or GA with the
antibiotic.

AB For the practical use of N₂O-treatment, an expt. was conducted to study
the following points; (a) effect of N₂O on fertilization, (b) production
of amphidiploids from cross-pollinated florets, and (c) improvement of
culture media for the treated wheat spikes. N₂O-treatment of pollinated
florets did not disturb fertilization, which seemed to proceed rather
normally. Polysperm fertilization resulting in triploidy was not induced.
N₂O appeared to inhibit specifically cell division after fertilization,
producing polyploid plants. By suitable treatment, all resulting
seedlings became polyploid. Amphidiploids can be directly produced by
treating cross-pollinated florets with N₂O. This was demonstrated in the

cross, *Triticum aestivum* .times. **Secale cereale**. The supplement of glucose as a C source to culture media of the N₂O-treated spikes had only a slight effect on seed setting but improved markedly the endosperm development and, consequently, germination. This, in turn, allowed polyploid embryos a better chance to survive. The supplement of penicillin as an **antibiotic** to the culture media did not improve seed setting, endosperm development, and germination, but an increase in polyploidy occurrence was noticed. From Japan Sci. Rev., Biol. Sci. 13, 203(1962) (Pub. 1964).
